Abstract

Analysis of the collective structure of $K^\pi = 0^+$ states in terms of phonon excitations for great amount of nuclei is presented. It is shown that the rotational bands built on these states strongly depend on their structure. The spectrum of the bands is obtained by the application of the Nuclear Surface Oscillation /NSO/ model and assumption of "Kassini form" for the nuclear shape. The yrast lines energies can be successfully described by the crossing of the different rotational " β - bands", if the collective structure of these band heads is properly taken into account.

Great amount of theoretical and experimental investigations are dedicated to the analysis of the excited 0^+ states and the bands built on them [1]. These investigations show that in the deformed nuclei the dependence of the energies of the rotational bands on the angular momentum L is qualitatively similar for the ground band and the " β - bands" constructed on each of these states. Therefore in first approximation these bands may be considered without including the band head structure. Nevertheless the influence of the 0^+ states structure on the rotational spectra is very important. In order to explain the quantitative differences in the rotational bands on the different band heads, as well as the energies and transition probabilities of the yrast lines we have to take into account their collective structure. This leads to the idea to link the structure of the $K^\pi = 0^+$ states to the changes in behavior of rotational bands built on them. Thus it is straightforward to examine some simplified models of the rotational bands of deformed nuclei, in which the dependance on the collective structure of the 0^+ states is considered. Further we can explain the yrast line behavior and structure as a result of the band crossings of these rotational bands.

For this purpose in this paper we first study the low-energy 0^+ spectra of a large amount of the even-even nuclei from the heavier nuclear shells, where most of the deformed and transitional nuclei are observed. It is easy to check that the energies of the 0^+ excited states may be described by simple phenomenological formula :

$$E_n = An - Bn^2 \quad (1)$$

as a function of integer classification parameter n . In (1) A and B are fitting parameters, n is an integer number corresponding to each of the 0^+ excited state. We can define the physical meaning of the integer classification quantum number n , as the number of monopole phonons that determine the collective structure of 0^+ excited state.

Let us consider the collective Hamiltonian:

$$H = \alpha R_+^j R_-^j + \beta R_0^j R_0^j + \frac{\beta \Omega^j}{2} R_0^j \quad (2)$$

with interaction parameters α , β and $\Omega^j = \frac{2j+1}{2}$.

In (2) H is written in terms of the monopole phonon operators R_+^j , R_-^j and R_0^j constructed from the fermion creation and annihilation operators $\alpha_{jm}^\dagger$, α_{jm} , confined on a j -orbit with projections $m = -j, \dots, j$ as:

$$\begin{aligned} R_+^j &= \frac{1}{2} \sum_m (-1)^{j-m} \alpha_{jm}^\dagger \alpha_{j-m}^\dagger; & R_-^j &= \frac{1}{2} \sum_m (-1)^{j-m} \alpha_{j-m} \alpha_{jm}, \\ R_0^j &= \frac{1}{4} \sum_m (\alpha_{jm}^\dagger \alpha_{jm} - \alpha_{j-m} \alpha_{j-m}^\dagger), \end{aligned} \quad (3)$$

The operators R_+^j , R_-^j and R_0^j satisfy the commutation relations :

$$[R_0^j, R_\pm^j] = \pm R_\pm^j; \quad [R_+^j, R_-^j] = 2R_0^j \quad (4)$$

In order to simplify the notations further we will omit the indices j .

Let us now present this Hamiltonian in terms of "ideal" boson creation and annihilation operators $[b, b^\dagger] = 1$; $[b, b] = [b^\dagger, b^\dagger] = 0$ using the Holstein-Primakoff transformation [4] for the operators R_+ , R_- and R_0 :

$$R_- = \sqrt{2\Omega - b^\dagger b} b; \quad R_+ = b^\dagger \sqrt{2\Omega - b^\dagger b}; \quad R_0 = b^\dagger b - \Omega \quad (5)$$

These transformations conserve the commutation relations between R_+ , R_- and R_0 operators. Thus for the Hamiltonian (2) in terms of the new boson creation and annihilation operators ("ideal" bosons) $b^\dagger$, b we have:

$$H = A b^\dagger b - B b^\dagger b b^\dagger b \quad (6)$$

The coefficients in (6) are related to the old ones as $A = \alpha(2\Omega + 1) - \beta\Omega$; $B = \alpha - \beta$.

Therefore the energy of any monopole excited state $|n\rangle = \frac{1}{\sqrt{n!}} (b^\dagger)^n |0\rangle$, where $b|0\rangle = 0$ can be obtained as:

$$\langle n | A b^\dagger b - B b^\dagger b b^\dagger b | n \rangle - \langle 0 | A b^\dagger b - B b^\dagger b b^\dagger b | 0 \rangle = E_n = A n - B n^2 \quad (7)$$

The Hamiltonian (6) creates the same energy spectrum as the phenomeno-

logical formulae (1) if the integer classification parameter n is interpreted as the number of ideal bosons .

Now we can label every $K^\pi = 0^+$ state by an additional characteristic n - number of monopole bosons determining it's collective structure. The parameters α and β of (2) are evaluated by fitting the experimental energies of the different 0^+ states of a given nucleus to the theoretical ones for all possible distributions of the classification numbers n . Some of our calculations corresponding to the distributions with minimal value of χ -square along with the experimental data are presented on **Figure 1**.

There is a relatively good agreement with experiment even in the case of ^{194}Pt having eight 0^+ states. It is very important to point out that the ordering of the states in respect to their number of phonons does not correspond to increase of energy. For most of the nuclei the lowest excited $K^\pi = 0^+$ states have more collective nature (larger n) than the states with higher energies. The values of the parameters α and β for some of the considered nuclei are given in **Table 1**.

Table 1. Values of hte parameters a and β for some nuclei.

Nucleus	^{114}Cd	^{156}Gd	^{158}Er	^{168}Yb
a	1.19593	1.17889	1.23148	1.17889
β	0.28923	0.397842	0.21933	0.397842
Nucleus	^{172}Yb	^{178}Hf	^{188}Os	^{194}Pt
a	1.3206	1.21661	0.762154	0.763518
β	0.35529	0.318346	0.101847	0.072

The next step is the investigation of the rotational " β -bands" build on the already considered as band heads 0^+ states. We use the standard quantum rigid rotator approach, in which energies of the states belonging to a given rotational band :

$$E_{rot}(L) = \frac{L(L+1)}{2\mathcal{F}} \quad (8)$$

are determined by the moment of inertia $\mathcal{F}$. In order to obtain it, we restrict ourselves to nuclei with axial symmetry and uniform density distribution. In our approach we use the Kassini form for the description of the nuclear surface. In the YZ plane this form is expressed as:

$$Y^2 = \sqrt{c^4 + 4a^2 Z^2} - a^2 - Z^2$$

and is plotted on **Figure 2**. The radius of the sphere inside the plain cross section $R_{sph} = \sqrt{a^2 - c^2}$ and the maximal distance from the center $R_{max} = \sqrt{a^2 + c^2}$ are conveniently expressed by means of the parameters a and c and illustrate their meaning.

The choice of the Kassini form, which depends on only two parameters a and c , is determined by its simplicity and the possibility to get exact, analytical expressions for many physical observables depending on the nuclear shape. For instance the main component of the tensor of inertia in the case of rotation around fixed Y axis (see Figure 2) is:

$$\begin{aligned} \mathcal{F}_y = & m\rho_0 \frac{\pi (2 \sqrt{a^2 + c^2} (16 a^6 - 8 a^4 c^2 + 246 a^2 c^4 + 15 c^6))}{960 a^2} + \\ & m\rho_0 \frac{\pi \left(15 c^8 \log\left(\frac{c^2}{2 a^2 + c^2 + 2 a \sqrt{a^2 + c^2}}\right) - 240 a^4 c^4 \log\left(\frac{2 a^2 + c^2 + 2 a \sqrt{a^2 + c^2}}{c^2}\right) \right)}{960 a^3} \end{aligned} \quad (9)$$

In the expression (9) m is the mass of the nucleons, A is a nucleus mass number and $\rho_0 = \frac{A}{V(a,c)}$ is the value of the matter density in the nucleus, where $V(a,c)$ is its volume:

$$V(a,c) = \frac{2R_{\max} \left(R_{sph}^2 - a^2 \right) \pi}{6} + \frac{c^4 \pi \text{ArcSinh}\left(\frac{2a}{c^2 \sqrt{\frac{1}{a^2 + c^2}}}\right)}{2a} \quad (10)$$

Another important quantity is the mean square radius, which is obtained to be:

$$R_{ms}^2(a,c) = \frac{a \left(4 a^4 + 24 c^4 - 2 a^2 c^2 - 15 a c^4 \sqrt{\frac{1}{a^2 + c^2}} \log\left(\frac{c^2 + 2 a (a + \sqrt{a^2 + c^2})}{c^2}\right) \right)}{\frac{3 c^4 \text{ArcSinh}\left(\frac{2 a \sqrt{a^2 + c^2}}{c^2}\right)}{\sqrt{a^2 + c^2}} - 20 a^3 + 10 a c^2} \quad (11)$$

In the realistic applications to the nucleus we are going to use instead of the component $\mathcal{F}_y$ of the tensor of inertia the difference $\mathcal{F} = \mathcal{F}_y - \mathcal{F}_{sph}$, where the moment of inertia $\mathcal{F}_{sph}$ corresponds to the sphere with radius $R_{sph} = \sqrt{a^2 + c^2}$ (see **Figure 2**) and is given by:

$$\mathcal{F}_{sph} = m\rho_0 \frac{8 (c^2 - a^2)^{\frac{5}{2}} \pi}{15} \quad (12)$$

As a result in the case of nuclei with spherical symmetry we directly come to $\mathcal{F} = 0$ because of the condition $a = 0$ for the Kassini form. The use of the difference $\mathcal{F}$ is further approved by the realistic values of mean square radii without the necessity to involve additional parameters. Among the advantages of the Kassini form one can point out that it permits easy introduction of different proton and neutron density distributions, which gives possibility to introduce other types of collective motion, for instance "scissors-type" modes etc.

Now we will make use of the quantity ΔA which is the difference between the particles in the whole nuclear volume and the ones in the sphere inscribed in the middle of the Kassini form, which we consider as the number of nucleons responsible for the rotational motion:

$$\Delta A = \frac{\rho_0}{6} \pi \left(\sqrt{a^2 + c^2} (2c^2 - 4a^2) + \frac{3c^4}{a} \text{ArcSinh}\left(\frac{2a}{c^2 \sqrt{\frac{1}{a^2 + c^2}}}\right) - 8(c^2 - a^2)^{\frac{3}{2}} \right) \quad (13)$$

Finally, to link our moment of inertia $\mathcal{F} = \mathcal{F}_y - \mathcal{F}_{sph}$ with the number of bosons of any $K^\pi = 0_n^+$ state we imply the results of the Nuclear Surface Oscillation Model [3] and apply the recently derived [4] expressions for the commutation relations :

$$[b^n, (b^\dagger)^m] = \begin{cases} \sum_{l=0}^{n-1} \frac{m!}{(m-n+l)!} \binom{n}{l} (b^\dagger)^{m-n+l} b^l & n \leq m \\ \sum_{l=0}^{m-1} \frac{n!}{(n-m+l)!} \binom{m}{l} (b^\dagger)^l b^{n-m+l} & n \geq m \end{cases} \quad (14)$$

The following expression of the mean square radius of spherical nucleus with uniform density, in a collective excited state $|n\rangle$:

$$R_{ms}^2(n) = \frac{3c^2 \left(32\pi^2 + 80n\pi \frac{E_0}{C_0} + 15(-1+n)n \left(\frac{E_0}{C_0} \right)^2 \right)}{160\pi^2 + 60n \frac{E_0}{C_0}} \quad (15)$$

$$\text{if } n = 0 \text{ we have } R_{ms}^2(0) = \frac{3c^2}{5}$$

is obtained in the Nuclear Surface Oscillation Model [3]. E_0 is the one-phonon excitation energy, C_0 - nuclear surface compressibility parameter and c is the radius at half density .

Taking into account that the ratio of $\frac{E_0}{C_0} \ll 1$ and imposing the restriction, that the dependence of the mean square radius on the number of bosons in our case (11) and the spherical case $R_{ms}^2(n)$ (15) are the same , after some algebraic calculations we obtain the dependence of the parameter a on n . The parameter a separated in two terms:

$$a(n) \approx a + \Delta a(n),$$

where the part directly related to the collective motion is:

$$\Delta a(n) = \frac{\sqrt{\frac{3}{5}} \sqrt{c^2 n \frac{E_0}{C_0} \left(8\pi^2 (-3+20\pi) + 3(-10\pi^2 + n(3-20\pi+10\pi^2)) \frac{E_0}{C_0} \right)}}{8\pi^2} \quad (16)$$

As a result, the moment of inertia $\mathcal{F} = \mathcal{F}_y - \mathcal{F}_{sph}$ becomes the following function of n - the number of phonons :

$$\mathcal{F}(a, c) = \mathcal{F}_y[a + \Delta a(n), c] - \mathcal{F}_{sph}[a + \Delta a(n), c] \quad (17)$$

We apply this expression (17) in our calculations of realistic nuclear systems, at the same time fixing the value of the parameter $c = 1.286A^{\frac{1}{3}}$, where A is the mass number. In **Figure 3** we present the dependence of ΔA (13), the moments of inertia $\mathcal{F}_y$ and $\mathcal{F}(a, c)$ (multiplied by 10^{-3}) and the mean square radius on the parameters of the Kassini form. ΔA in each case is less than the number of valent nucleons (some indication of the role of super-conductivity). $\mathcal{F}(a, c)$ increases with a to its limiting value, corresponding to the rigid moment of inertia $\mathcal{F}(c, c)$. For instance in the case of ^{174}Hf $\mathcal{F}(c, c) = 13489.5 \text{ Mev fm}^2$.

Now we have all the necessary tools to calculate the energies of rotational bands. Using formula (1) we first analyze the distribution of 0^+ states for the nuclei under consideration. Then with the fixed number of phonons n for each band head, we fit the model parameter a entering in the moment of inertia (17) from the experimental ground state ($n = 0$) rotational band using (8). The second parameter $\frac{E_0}{C_0}$ can be determined from any rotational band built on excited 0^+ state. We choose the one built on the lowest in energy of the excited band heads. There is nothing amazing in the fact that using the crossing of rotational bands we could successfully describe the energy behavior of the yrast lines in the cases of ^{174}Hf , ^{168}Yb . It is surprising, although that we have extremely good agreement with experiment using only two fitting parameters a and $\frac{E_0}{C_0}$, and applying simple "rigid rotator" model (8). Our results (shown with lines) along with the experimental data and the values of the model parameters are presented on **Figures 4 and 5**. On **Figure 6**, we present the results of our calculations of rotational bands for the nucleus ^{168}Yb in the case when $n = 0$ for all the bands heads. This example illustrates the importance of including the bands heads' structure in the calculation of the spectrum of the rotational bands.

We introduce the quantity $\beta_K = \frac{R_{\max} - R_{sph}}{R_{sph}}$, which we consider as a measure of the deformation of the nuclear system. As mentioned above the values of the mean square radii R_{ms} and also the "deformations" β_K are relatively realistic and in very good agreement with the corresponding values obtained in the HFB approach [5]. Comparison of the corresponding values are shown in **Table 2**.

Table 2. Values of model parameters and comparison with HFB data [5].

	^{168}Yb	^{174}Hf
a	3.65	3.50
R_{ms}	5.31	5.39
$^{(HFB)}R_{ms}$	5.298	5.365
β_K	0.31	0.27
$^{(HFB)}\beta$	0.317	0.317
$\frac{E_0}{C_0}$	0.015	0.013

It is important to point out the particular behavior of the mean square radius, as a function of a (see **Figure 3**). It has a minimum in the region close to the estimated values of this parameter. In the future, it is interesting to investigate this phenomena from physical point of view.

There is a small difference between our calculations of the energies and their experimental values at the angular momenta, where the "back bending" may occur. This is more explicit on **Figure 7**, where we present the behavior of the first derivatives of the calculated and experimental yrast-lines energies, in respect to the angular momentum L . The explanation of the mechanism of phase transition, caused by the jump from the ground band to another bands that may take place is a very interesting problem, but was not exactly the aim of this paper. We have prepared a reasonable background for such an investigations.

The presented results are rather convincing for the possibility of this phenomenological approach, assuming the Kassini form for the nuclear system, to describe the rotational bands built on the 0^+ states with the input information about their structure as the band heads. Even more the structure of the yrast band is accurately reproduced by the behavior of these rotational bands. On the other hand, applying this model to the analysis of the yrast lines one can get the direct information about the collective structure of the 0^+ states that appear as band heads of corresponding crossing rotational bands, which form it. Also, applying our results for the yrast band to the traditional variable moment of inertia approaches $\mathcal{F}(L)$, one can find more reasonable physical meanings of their model parameters, together with the explanation of the behavior of energies in the regions of crossing of the different rotational bands.

I thank sincerely A. Georgieva, V. Zamfir, C. Giusti and M. Soitsov for fruitful discussions and help.
